John von Neumann suggested in 1946 a method to create a sequence of pseudo-random numbers. E idea is known as the "middle-square"-method and works as follows: We choose an initial value a which has a decimal representation of length at most n. We then multiply the value a_0 by itself, ac leading zeros until we get a decimal representation of length $2 \times n$ and take the middle n digits to for a_i. This process is repeated for each a_i with $i > 0$. In this problem we use $n = 4$.

Example 1: $a_0 = 5555$, $a_0^2 = 30858025$, $a_1 = 8580$, ...

Example 2: $a_0 = 1111$, $a_0^2 = 01234321$, $a_1 = 2343$,...

Unfortunately, this random number generator is not very good. When started with an initial val it does not produce all other numbers with the same number of digits.

Your task is to check for a given initial value a_0 how many different numbers are produced.

Input

The input contains several test cases. Each test case consists of one line containing a_0 ($0 < a_0 < 10000$ Numbers are possibly padded with leading zeros such that each number consists of exactly 4 digit The input is terminated with a line containing the value '0'.

Output

For each test case, print a line containing the number of different values a_i produced by this rando number generator when started with the given value a_0. Note that a_0 should also be counted.

Note that the third test case has the maximum number of different values among all possible input

Sample Input

```
5555
0815
6239
0
```

Sample Output

```
32
17
111
```
